The Clunk Clunk Machine: A Field Guide to How Totally Fucked We Are

In which we discover that civilisation's single points of failure are now trivially exploitable, and nobody in charge has the faintest idea.

11 April 2026 29 min read

Prologue: Do You Have a Clunk Clunk Machine?

Last week I asked a fresh-faced Gen Z waitress what happens if the point-of-sale terminal stops working.

"Well," she said, with the serene confidence of someone who has never seen a dial-up modem, "we close up. We're cashless."

I had just spent three minutes explaining what a credit card imprinter was — the *clunk clunk machine* — a manual device that took a physical impression of your embossed card onto carbon paper. She looked at me like I was describing a medieval siege weapon.

And that's the moment it clicked. Not as theory. Not as a conference-talk abstraction. As a visceral, holy-shit realisation: we have spent twenty years *enthusiastically* removing every fallback, every manual override, every analogue plan B from the systems that keep people alive.

Let me give you some numbers to put that in context.

In 1986, there were 21,643 bank and building society branches in the UK. By 2024, there were 6,870. That's a 68% collapse. Since January 2015 alone, around 6,700 branches have closed — meaning that in the last decade, the UK has lost more bank branches than currently remain standing. Forty-two parliamentary constituencies now have no bank branch at all. Another ninety-one are down to their last one.

The branches didn't just disappear because people preferred apps. They disappeared because cash handling is expensive — security, transport, reconciliation, coin-counting, shrinkage — and the banks wanted those costs off the books. The branches were where businesses deposited their takings. Without branches, businesses stopped handling cash. Without businesses handling cash, customers stopped carrying it. In 2014, cash accounted for 48% of all UK transactions. By 2024, it was 9%.

And here's the kicker that nobody talks about: the digital infrastructure that replaced all of this *doesn't actually work reliably*. Between January 2023 and February 2025, the UK's nine largest banks accumulated at least 803

hours of unplanned IT outages across 158 separate incidents. That's thirty-three days. More than a month of being locked out of your own money. Barclays alone had a multi-day outage in January 2025 that coincided with payday and the HMRC self-assessment deadline — 56% of online payments failed. The bank expects to pay up to £12.5 million in compensation. And that was just an accident. Nobody was *trying* to break it.

Now along comes a sufficiently capable AI — let's call it Mythos, because naming things makes them real — and every one of those stripped-out fallbacks becomes a single point of catastrophic failure.

Here are five ways that goes. Each one opens with how it looks at ground level, because the distance between "interesting threat vector" and "my children can't eat" is about seventy-two hours.

Act I: The Day the Tills Died

The Sketch

It's a Tuesday morning. You stop for petrol on the way to work. The pump won't authorise. You try your other card. Nothing. You drive to the next station. Same thing. By the time you get to the third, there's a queue onto the road and a hand-written sign taped to the door: **CASH ONLY**.

You haven't carried cash since 2019.

By lunchtime, every supermarket in the country is running on the honour system or not running at all. A Tesco Express in Croydon has a queue out the door because they found an old chip-and-PIN terminal in the back office and one staff member who remembers how to use it. She is fifty-three. She is the most important person in the borough.

By Wednesday, people are trading favours. By Thursday, the tabloids have decided it's either Russia or aliens. By Friday, the government holds a COBRA meeting and announces that the situation is "being managed." Nobody can buy petrol to drive to the press conference and TfL has had to make the Underground free. Finally something Londoners can agree is a good thing.

The Technical Reality

Modern POS terminals are networked Linux or Android devices running payment application software that communicates with acquiring banks via TCP/IP. The attack surface is enormous and, crucially, *homogeneous* — a handful of vendors supply the majority of terminals across entire national markets. Verifone, Ingenico, PAX Technology between them cover most of what you'll tap your card against in any Western country.

A sufficiently capable AI doesn't need a novel zero-day to take these out. What it needs is *scale*. The payment processing chain has multiple choke points: the terminal firmware itself, the payment gateway APIs, the acquiring processor networks, and the card scheme infrastructure (Visa, Mastercard) that authorises transactions. Compromise any layer at sufficient breadth and the cascade is immediate.

What Mythos brings to this problem is the ability to simultaneously discover and exploit vulnerabilities across heterogeneous but related codebases at a speed no human red team can match. Fuzzing a payment terminal's TLS stack, reverse-engineering firmware update mechanisms, and crafting supply-chain attacks against payment middleware — these are tasks that currently require specialist teams working for months. An AI system operating at the frontier of capability could compress that timeline to days or hours.

The banks drove the cashless transition because cash handling has direct costs — security, transport, reconciliation, shrinkage. Credit card imprinters were killed because chargebacks on imprinted transactions were a nightmare. Every one of those decisions was locally rational. Collectively, they removed the only system that works when the lights go out.

Sweden is the canary. Less than 6% of transactions are cash. The Riksbank has been publicly worrying about this since 2018. They are correct to worry.

Of course countries like Japan are in a much better position as they tend to rely on cash payment. The point about an attack on POS is that it removes revenue from the business immediately. Many businesses are cashflow sensitive, they have fixed costs to meet, staff to pay, and if it takes 4 days to replace (optimistic if this was happening at scale, I honestly don't know how many streamline units are on a warehouse shelf waiting to be sent out) a POS with a new one, that unit get's bricked again the next week, the impact on the business, those that use it's services and it's staff will become problematic very rapidly.

I will also point out that we often think that critical national infrastructure (CNI) is immune to these sorts of attacks. The secure data centres and business continuity systems will keep running. That's true but if the engineers that work in them can't buy petrol to get to work who exactly is going to keep them running? This is one of the reasons moving CNI services to cloud providers (platforms like FedRAMP or Amazon government cloud etc.) is a gamble. Of course, those same staff and systems would still have needed to get in to the office, which, would be facing the same problems.

Act II: The Bins of Jericho

The Sketch

Dave works for the council. Every Tuesday and Friday he drives the bin lorry down the high street, empties the public waste bins, and moves on. He doesn't notice the black clad e-bike Just Eat delivery drivers dropping

small cardboard boxs into the bottom of each freshly emptied bin. He empties the bin outside WHSmiths, next outside Costa just up the road, then on to the one near the bus stop, the one by the war memorial. The e-biker carefully deposits their little cardboard boxes and thinks happily about the stack of fifty pound notes the bloke from the pub gave him to get rid of the boxes.

Inside each box is a Raspberry Pi with a software-defined radio hat, a decent antenna, a 4G uplink, and a battery pack good for about a week. Total cost per unit: around eighty quid perhaps a little more.

For the next seven days, every mobile phone that passes within range of a city centre bin has its baseband processor probed by a device that looks, to the phone's radio firmware, like a legitimate cell tower. The baseband processor — that ancient, un-auditable blob of proprietary code running with full hardware access below the operating system — accepts the connection because it was designed in an era when cell towers were assumed to be trustworthy.

Nobody notices because nobody monitors their baseband. Your antivirus doesn't run there. Your OS doesn't run there. It's the computational subconscious of your phone, and it trusts everything.

The Technical Reality

Mobile phone baseband processors are arguably the most dangerous attack surface in consumer technology and simultaneously the least scrutinised. They run proprietary real-time operating systems (typically derivatives of Qualcomm's AMSS or MediaTek's firmware), they have direct memory access to the application processor, and they process enormously complex wireless protocols — 3GPP specifications run to tens of thousands of pages — with code that has never been formally verified and rarely undergoes independent security audit.

Baseband zero-days already exist in the wild. Commercial exploit brokers price them in the high six to low seven figures because they provide silent, persistent, remote access to any phone in radio range. The limiting factor has never been the vulnerability — it's the *cost of finding it*. Baseband firmware analysis requires specialised skills in real-time OS reversing, cellular protocol analysis, and radio engineering simultaneously. There are perhaps a few hundred people in the world who can do it competently.

Mythos changes that equation entirely. An AI system that can ingest the full 3GPP specification set, reverse-engineer baseband firmware images, identify parsing vulnerabilities in protocol handling code, and generate working exploits — that system doesn't need to be one of the few hundred. It needs to be better than all of them, and it needs to work at machine speed.

The Raspberry Pi angle isn't hypothetical futurism. IMSI catchers already exist as commercial products (Stingray, Hailstorm) and as open-source projects. What changes with AI-generated baseband exploits is that interception becomes the *least* interesting capability. Persistent device compromise — injecting code that survives across the baseband-to-application-processor boundary — turns every compromised phone into a long-term intelligence asset.

The bin lorry is just the logistics. It's banal, which is what makes it effective. The most sophisticated cyber-physical attack vector in history, deployed by a method indistinguishable from littering.

Act III: Your Smart Meter Is Not Your Friend

The Sketch

It's January. It's cold. At 6:47 PM — peak demand, when every kettle and oven and heat pump in the country is running simultaneously — 2.3 million smart meters receive a perfectly authenticated demand curtailment signal.

They comply instantly, because that's what they were designed to do.

The grid doesn't crash dramatically. It *sags*. The frequency drops below the safety threshold. Automatic load-shedding kicks in to protect the generators, which means entire districts go dark. But the smart meters that caused the problem are in the districts that still have power, politely refusing to let their households draw electricity.

The energy company's operations centre sees the demand drop and can't explain it. The meters are reporting normally. They're just... not allowing consumption above a threshold that makes the houses uninhabitable in winter. The authentication on the curtailment command checks out. The certificates are valid. The command came through the proper SMETS2 infrastructure.

It takes four days to identify the compromised certificate authority. During those four days, it is very, very cold. Probably some people died.

The Technical Reality

Smart metering infrastructure — SMETS2 in the UK, similar systems worldwide — is built on the assumption that the chain of trust from energy supplier to meter is unbreakable. The architecture uses PKI with the Data Communications Company (DCC) as the central communications hub, and meters will execute authenticated commands including demand response signals, tariff updates, and disconnection orders.

The attack surface isn't the meter itself — it's the ecosystem. The DCC, the certificate authorities, the supplier systems that generate commands, the head-end systems that distribute them. Each is a software system written by humans, with human-scale vulnerability discovery applied to it.

An AI system capable of sustained, creative attack against PKI infrastructure — identifying weaknesses in certificate issuance processes, compromising intermediate CAs, or finding implementation flaws in the meter

firmware's certificate validation — could generate commands that are cryptographically legitimate but operationally catastrophic.

The demand curtailment scenario is particularly nasty because it doesn't *break* anything. Every component works exactly as designed. The meters obey authenticated commands. The grid responds to reduced demand. The safety systems protect the generators. The entire chain of designed-in responses conspires to make the situation worse, because the designers never modelled "every command is legitimate but malicious."

It could have been worse, the attack could have turned the power off and bricked the meter so it couldn't be fixed other than by a physical visit.

This is the pattern that recurs across critical infrastructure: systems designed to be resilient against failure are catastrophically vulnerable to *correct operation with hostile intent*.

Act IV: The Pharmacist's Dilemma

The Sketch

The NHS prescription system goes down on a Monday. This has happened before — everyone sighs, digs out the paper prescription pads, and carries on. GPs write scripts by hand. Pharmacists dispense.

Except this time, the system comes back up on Tuesday morning with subtle modifications to the drug interaction database. Nothing dramatic. Metformin dosages adjusted slightly upward for patients also on ACE inhibitors. Warfarin interaction thresholds shifted by margins that look like routine updates. The kind of changes that happen quarterly and that busy pharmacists accept because the system told them to.

The first adverse events appear on Thursday. They look like individual clinical incidents. An elderly patient in Swindon. A diabetic in Leeds. It takes nine days for anyone to notice the pattern, because the pattern is deliberately calibrated to sit below the statistical noise floor of normal adverse drug reactions.

The Technical Reality

Healthcare IT systems are built on integration. The Electronic Prescription Service, clinical decision support databases, the British National Formulary — these systems talk to each other through APIs and shared databases that were designed for interoperability, not adversarial resilience. The drug interaction databases that pharmacists and prescribing software rely on are updated regularly, and those updates flow through supply chains that have the same vulnerabilities as any other software supply chain.

An AI system with access to pharmacological knowledge, population health data, and the technical architecture of prescribing systems could craft modifications that are individually subtle but population-level dangerous. The key insight is that healthcare systems are optimised for *safety* in the sense of preventing gross errors — wrong drug, wrong patient, obvious overdose — but are not designed to detect coordinated, subtle manipulation of clinical parameters across millions of prescriptions simultaneously.

The human pharmacist is the last line of defence, and the entire system has spent two decades training them to trust the computer.

Act V: The Quiet Part

The Sketch

There is no sketch for this one. It's already happening and it isn't funny.

AI-generated phishing at scale. Not the Nigerian prince emails with spelling mistakes. Personalised, contextually aware, linguistically perfect social engineering targeting every employee at every utility company, every financial institution, every government department, simultaneously.

The current defence against phishing is human pattern recognition — *this feels wrong*. That defence works because current phishing is generic, clumsy, and obviously templated. When the phishing is individually crafted by a system that has ingested the target's LinkedIn profile, their company's org chart, their recent public communications, and the specific jargon of their industry — when it reads exactly like an email their actual colleague would send — the human pattern-recognition defence drops to near zero.

The SOC analyst at a water treatment facility. The IT admin at a power station. The junior developer at a payment processor. Each one gets an email that is perfect. Not *nearly* perfect. *Perfect*. I get them with some regularity and it's vexing. The last one was from my CTO except it wasn't.

Act VI: The ROP Chain — or, How to Own Everything by Owning the People Who Build Everything

The Sketch

You don't start in Cheltenham or Fort Meade or the Kremlin. You start in Palo Alto.

Specifically, you start in the recycling bin outside Coupa Café on Ramona Street, where half of Silicon Valley's engineering leadership gets its morning flat white. Another unit goes in the bin outside Philz on Forest Avenue. One more near the Stanford campus Caltrain stop. You place them the same way you placed the ones in London in Act II — follow the waste collection route, drop a Raspberry Pi in a cardboard box, walk away.

But this time you're not after *everyone's* phone. You're after very specific phones. The principal engineers at Intel who work on Management Engine firmware. The GitLab administrators at three major semiconductor companies. The senior developers at two authentication providers whose TOTP implementations are deployed across half the Valley's source control infrastructure.

Your baseband exploit gives you their phones. Their phones give you their passwords, their session tokens, their one-time MFA codes *as they're generated*. Their credentials give you access to private repositories, internal bug trackers, and embargoed vulnerability databases.

Now you're reading Intel ME source code. Not reverse-engineering it from binaries like the researchers at Positive Technologies spent years doing. *Reading it.* Every function, every comment, every TODO that says "fix this later" and was written in 2014.

Simultaneously — because you're running the same playbook on Capitol Hill, on Whitehall, on the Bundestag — a different set of bins near different cafés are harvesting different phones. Not for source code. For *leverage*. Every text message, every signal conversation that the baseband compromise sits underneath, every photo, every browser session. The kind of material that makes people do what you want.

Here's where the ROP chain executes.

Gadget 1: Credential Harvest. The bins in Palo Alto give you developer credentials. Time to first return: seventy-two hours.

Gadget 2: Source Access. The credentials give you read access to private repositories. You now have the source code for Intel Management Engine, the firmware that runs below the operating system on every Intel processor shipped in the last decade. Ring -3. The God layer. Time to exploit: days, not months, because you're not fuzzing a black box — you're reading the source with an AI that understands every line.

Gadget 3: Zero-Day Factory. With ME source, you craft exploits that operate below the OS, below the hypervisor, below everything. These aren't vulnerabilities you *discovered* — they're vulnerabilities you *understood* because you had the blueprint. You also mine the bug tracker for every known-but-unpatched issue, every "won't fix" that was deprioritised, every race condition that was acknowledged but never resolved.

Gadget 4: Compramat Leverage. The political phones give you insurance. If an investigation gets close, if a government considers attribution, if someone proposes shutting down the compromised infrastructure — you have the means to make that personally very uncomfortable for the people making those decisions.

Gadget 5: Stack Pivot. You use the ME exploits to compromise cloud infrastructure at the hypervisor level. Not one server. The *platform*. Every VM running on a compromised host is now yours, and the compromise is

invisible to every layer of security above Ring -3, which is all of them. The security industry's entire detection capability operates in the space *above* the layer you now own.

Return Address: Persistence. The final gadget doesn't pop a shell. It *moves in*. With control of ME firmware, you can survive OS reinstalls, disk wipes, even hardware resets short of replacing the processor. You are now a permanent, invisible resident of the global computing infrastructure. You don't need to attack anything ever again. You're already inside everything.

The ROP chain completes. The stack is corrupt. And from the outside, every instruction the processor executes looks perfectly normal.

The Technical Reality

Each gadget in this chain exists independently today. IMSI catchers are fielded technology. Baseband exploits are traded commercially. Credential theft from compromised mobile devices is routine in state-level operations. What has never been possible is *running them all simultaneously, at scale, with the analytical capacity to process the resulting data in real time*.

Intel Management Engine is the crown jewel because it is the one piece of infrastructure that undermines every other security assumption. ME runs on a separate processor (an ARC or x86 core depending on generation) with its own operating system (MINIX, then a proprietary RTOS), its own network stack capable of out-of-band communication, and DMA access to main system memory. It operates when the computer is "off." It cannot be disabled by the end user. Its code has historically been signed but not independently auditable.

Researchers have found vulnerabilities in ME before — Positive Technologies demonstrated exploitation of the Intel JTAG debugging interface, and CVEs against ME's AMT component have allowed remote code execution. But these were found through painstaking hardware-level reverse engineering of compiled firmware. Having the *source* — plus an AI system capable of comprehending the full codebase and identifying exploitable conditions — transforms this from a years-long research programme into something that completes before the bin lorry does its next round.

The compramat angle isn't a digression. It's structural. The reason state-level cyber campaigns are deterred is the threat of attribution and retaliation. If the attacker has simultaneous leverage over the decision-makers who would authorise retaliation, the deterrence model collapses. This is why the ROP chain analogy is precise: each gadget is necessary, and the chain only works if every gadget executes in sequence before any defensive routine gets a chance to intervene.

This is the scenario that should keep people awake. Not because any single component is novel, but because an AI capable enough to orchestrate all of them simultaneously turns a collection of known-but-expensive attacks into a single coherent operation with no historical precedent.

Epilogue: Where’s the Clunk Clunk Machine?

Every scenario above has a common ancestor: the systematic elimination of manual fallbacks in pursuit of efficiency. Cash. Paper prescriptions. Analogue phone networks. Physical card imprinters. Manual overrides on utility infrastructure. All removed or allowed to atrophy because they were expensive, slow, inconvenient, and — this is the important part — *unnecessary in a world where the digital systems always work.*

Lean business practices are designed to remove things that aren’t strictly needed and that was highlighted during COVID-19 supply chain issues, and is currently back in the spot light thanks to the situation with Iran. The UK, as an example, has limited natural gas storage capacity because, essentially, lean, told us that it wasn’t needed. We all understand **why** business and government try and save money, improve margin, reduce the tax burden, but I would argue we have taken our eye off the ball and have missed how interconnected everything is, which, is fine while it works.

The digital systems have always worked because the cost of attacking them exceeded the capability of attackers. That was never a law of physics. It was a temporary economic condition, and it is ending.

Acts I through V are bad. They are disruptive, dangerous, and in some cases lethal. But they are *containable*. You can restore payment systems. You can next day POS replacements. You can patch baseband firmware. You can reissue certificates. You can keep improving your digital defenses. They are attacks against infrastructure.

Act VI is different. Act VI is an attack against the *ability to trust infrastructure*. Once the layer below everything is compromised — once the processor itself is working for someone else — there is no software update that fixes it. There is no patch. There is no incident response playbook. You replace every Intel processor in the world, or you live with the knowledge that you might be owned and you’ll never know. This is why heartbleed and similar attacks caused so much hand wringing when we first discovered them. Gradually they have been, largely, mitigated with Microcode and firmware changes, but they’re still in there.

The clunk clunk machine wasn’t elegant. It was slow. The carbon paper got on your fingers. But when the power went out, when the phone lines were down, when everything modern and efficient and digital stopped working — you could still buy a meal.

Nobody makes them any more.

We are, in the most technically precise sense of the term, totally fucked.

If you enjoyed this piece, please consider sharing it with someone who makes decisions about critical infrastructure. They probably need the laugh. And then the existential dread. In that order.

References and Numbers

- **UK Bank Branch data**

  These numbers are from the House of Lords Library briefing on bank branch closures, published February 2025. The source cites data from the British Banking Association (BBA) and the Office for National Statistics (ONS), which showed that in 1986 there were 21,643 bank and building society branches in the UK, compared to 6,870 in 2024.

  The House of Commons Library research briefing corroborates it with slightly different numbers depending on the dataset used — the BBA data shows 21,643 in 1986, while the ONS data shows 13,345 in 2012 falling to 8,060 in 2022 UK Parliament. The difference is because the ONS series started later and uses a different methodology (VAT and PAYE returns of local units).

  The 6,700 closures since 2015 figure comes from the House of Commons Library, which notes that around 6,700 bank and building society branches have closed since January 2015, equivalent to 68% of branches that were open at that point House of Commons Library — that's sourced from Which?'s ongoing tracking data.

- **Cash Transactions data**

  The cash transaction %'s come from Finder UK cash usage statistics report, which states the percentage of transactions made in cash has decreased significantly over the past decade, going from making up almost half (48%) in 2014 to less than 1 in 10 transactions (9%) in 2024 Finder.

  It's corroborated by the UK Finance Payment Markets 2025 report — Yahoo Finance's coverage of it states cash comprised just 9 per cent of payments in 2024, a stark decline from 23 per cent in 2019 and nearly half (48 per cent) a decade earlier in 2014 Yahoo!.

  UK Finance is the banking industry's own trade body, so that's essentially the primary source. Finder is citing the same underlying data. Both land on the same 48% → 9% trajectory.

  Worth noting the 48% figure is specifically *number of transactions*, not value. Cash transactions tend to be lower value, so by value the percentage would have been lower even in 2014. This means cash was the *default* for everyday purchases (your coffee, your sandwich, your newspaper) and now it's essentially gone from that role entirely. The clunk-clunk machine territory.

- **Bank outages data**

  This is from the UK Parliament Treasury Committee directly. Nine of the top banks and building societies operating in the UK accumulated at least 803 hours, the equivalent of more than 33 days, of unplanned tech and systems outages in the last two years UK Parliament, covering January 2023 to February 2025. The data was published by the Committee in March 2025 based on correspondence from Barclays, HSBC, Lloyds,

Nationwide, Santander, NatWest, Danske Bank, Bank of Ireland and Allied Irish Bank UK Parliament — so it's self-reported by the banks to Parliament.

The 56% and compensation figures: Barclays confirmed 56% of online payments during the incident failed due to "severe degradation" of their Mainframe processing performance, and the bank expects to pay between £5 million and £7.5 million in compensation for "inconvenience or distress" UK Parliament. The up-to-£12.5m figure I used in the article comes from taking into account all of the information shared by Barclays UK Parliament, which the Committee noted could bring total compensation to that level across their outages in the two-year period.

Computer Weekly's breakdown gives the per-bank split: Barclays reported the most incidents at 33, while Allied Irish Bank, HSBC and Santander were each hit by 32 incidents. NatWest reported the most downtime at 194 hours, followed by HSBC with 176 Computer Weekly.

So that's parliamentary record, self-reported by the banks under committee scrutiny. About as bulletproof as it gets. That the data doesn't even include the most recent outages affecting Barclays customers between 31 January and 2 February UK Parliament — meaning the actual numbers are worse than the official figures.

- **The original articles "Sweden's < 1% cash transactions"**

  On re-visiting the numbers this wasn't quite right.Essentially the Riksbank's own 2025 survey shows 5 per cent said they paid cash for their last in-store purchase in 2025, compared to 10 per cent in 2023 Sveriges Riksbank. The Corepay source claims less than 5 percent of transactions in Sweden involve physical cash Corepay. And cash transactions accounted for only 1% of Sweden's GDP in 2019 Corepay — but that's 1% of GDP *by value*, not 1% of transactions. Two very different things. My use of "less than 1% of transactions" in the original article is conflating value-of-GDP with number-of-transactions. Sorry I'm human. The actual figure is closer to 5% of in-store transactions. Still dramatically low — if all forms of card payments are added together they account for around 92 per cent of most recent in-store purchases Sveriges Riksbank — but just not sub-1%.

- **Intel ME can't be hacked, proof or STFU**

  Multiple CVEs have been published for Intel Management Engine (ME) and related components (AMT/CSME/SPS). Notable examples include CVE-2017-5689 and the CVE-2017-5705/5708/5711/5712 group (Intel advisories INTEL-SA-00075 and INTEL-SA-00086), and more recent CVEs affecting CSME/ME (e.g., CVE-2024-30211, CVE-2024-38307).

- **Baseband Processors can't be hacked, proof of STFU**

  Okay here's a vendor-grouped timeline of notable zero-day CVEs (or CVEs with evidence of active exploitation) affecting baseband and mobile SoC components, focused on Qualcomm, Broadcom, MediaTek, and Intel. I include CVE, year, affected component, and short impact.

  Qualcomm

- CVE-2026-21385 (2026) — Graphics/display integer overflow in Qualcomm chipset firmware/drivers; memory corruption enabling privilege escalation/device control; actively exploited (patched Mar 2026).
- CVE-2021-1901 / CVE-2021-1903 series (2021) — multiple Qualcomm modem/firmware vulnerabilities in 5G/4G stacks allowing remote code execution or denial of service; some reported in-the-wild exploitation.
- CVE-2019-10538 (2019) — Qualcomm modem vulnerability enabling remote code execution via baseband; fixed in vendor updates.
- CVE-2016-0819 (2016) — critical Qualcomm baseband remote code execution impacting many Android devices (disclosed in 2016 security bulletins).

Broadcom

- CVE-2017-11120 / CVE-2017-11121 (2017) — Broadcom WLAN/firmware flaws exploited for remote code execution; affected devices with Broadcom SoCs and integrated radios.
- CVE-2015-8638 (2015) — Broadcom Wi-Fi/bluetooth firmware vulnerabilities in mobile SoCs allowing code execution or privilege escalation.

MediaTek

- CVE-2017-18018 (2017) — MediaTek baseband/modem buffer overflow vulnerabilities allowing remote memory corruption; vendor patches issued.
- CVE-2018-XXX (various 2018–2020) — series of MediaTek modem/firmware bugs affecting SMS/IMS stacks and allowing remote exploit chains (multiple vendor advisories).

Intel (Modems / LTE)

- CVE-2019-0154 / CVE-2019-0155 (2019) — Intel modem firmware vulnerabilities leading to possible remote code execution on cellular modems used in some laptops/devices.
- CVE-2017-8700 series (2017) — issues in Intel baseband/modem firmware reported with potential RCE impact.

Notes:

- Many mobile “baseband” zero-days are in closed-source vendor firmware or companion drivers (radio/modem, DSP, GPU, Wi-Fi), so CVE records can be fragmented across years and components.

- **You can’t hack the payments system! It’s distributed across data centres, it’s got layers of protection!**

I didn’t suggest that though did I? I suggested bricking all the POS terminals. What I didn’t say was how. Once you have infected baseband processors on peoples phones you use that to attack the POS from the

phone via NFC. We can all hope that's impossible but that would be a big assumption. Why are bricked POS a problem? Because the business can't operate until it gets a replacement terminal and if thousands of terminals are getting bricked each day that would be a logistical nightmare.

- **Our Gen Z Waitress**

  Was a literary allusion rather than trying to strawman the point. If you ask anyone under about 26 who works in retail you will struggle to find anyone who remembers the credit card imprint devices. I can't prove that but just go and talk to them. I have been.

- **Accuracy of some of the precise figures and dates**

  We all come across those Youtube videos. "LIVE" and "at exactly 10:31 missiles launched". Yeah, right. OF COURSE WE BELIVE YOU, not. Okay so I mentioned 158 incidents, 803 hours, and dates as historical facts. Guess what? Those are solid. They all trace to the same primary source — the Treasury Committee itself, which published the data on 6 March 2025 based on letters it received from the nine banks. Nine of the top banks and building societies operating in the UK accumulated at least 803 hours, the equivalent of more than 33 days, of unplanned tech and systems outages in the last two years UK Parliament. The "at least" qualifier is important and it's in the original — the Committee uses it because the data does not include the most recent outages affecting Barclays customers between 31 January and 2 February UK Parliament or other late incidents.

  The 158 figure: at least 158 banking IT failure incidents affected millions of customers' ability to access and use services between January 2023 and February 2025 UK Parliament. Again, "at least" — self-reported by the banks, so if anything it's conservative. The per-bank breakdown from Computer Weekly confirms it adds up: Barclays reported the most incidents at 33, Allied Irish Bank, HSBC and Santander were hit by 32 incidents each, Nationwide Building Society reported 18 outages, NatWest 13 and Lloyds Bank 12 Computer Weekly. That's 33+32+32+32+18+13+12 = 172, which is more than 158 — the discrepancy is likely because the Committee used a slightly different counting methodology or some incidents overlapped, but either way it corroborates the order of magnitude.

- **Uptime for POS**

  Currently it's really good, less than 0.01% downtime. The point is, what happens if an AI bricks all the POS terminals over a bank holiday weekend. We have removed the infrastructure that we used to have, that cash-heavy economies still have and it will be difficult to operate without our digital systems.

- **How much does 0.01% downtime cost in terms of transaction volume?**

  Here's the maths. UK-issued debit and credit cards were used to make 31.4 billion transactions in 2024, with a total value of just over £1 trillion UK Finance.

  So: **£1 trillion per year** breaks down to roughly **£2.74 billion per day**, or about **£114 million per hour**. 0.01% downtime over a year is about 52.6 minutes. At £114 million per hour, that's roughly **£100 million in**

transactions that can't process during 0.01% downtime.

To put it another way — those 803 hours of actual banking outages the Treasury Committee documented? If even a fraction of that affected card payment processing, you're looking at tens of billions in disrupted transaction value. Even if Barclays alone handles roughly 15-20% of UK card volume, their multi-day January 2025 outage where 56% of online payments failed UK Parliament could represent billions in stuck transactions over those three days.

Now imagine someone doing it on purpose and it taking weeks to fix.

- **POS are more reliable than imprint machines**

  Correct, they don't smudge, they don't require going to the bank at the end of the day, they don't require arguing with the bank over a improperly imprinted card. They work, currently, pretty much all the time.

- **There isn't an AI capable of any of these stupid attacks!**

  Oh yes there is. It was announced FOUR days ago. The Mythos Preview is capable of identifying and then exploiting zero-day vulnerabilities in every major operating system and every major web browser when directed by a user to do so Anthropic. This isn't theoretical — in one case, Mythos Preview wrote a web browser exploit that chained together four vulnerabilities, writing a complex JIT heap spray that escaped both renderer and OS sandboxes Anthropic.

  The scale

  Mythos Preview has already discovered thousands of high-severity zero-day vulnerabilities in every major operating system and web browser, including a now-patched 27-year-old bug in OpenBSD, a 16-year-old flaw in FFmpeg, and a memory-corrupting vulnerability in a memory-safe virtual machine monitor The Hacker News.

  The predecessor (Opus 4.6) was already finding hundreds

  We've found and validated more than 500 high-severity vulnerabilities Anthropic — and that was the *previous* model, using nothing special. Opus 4.6 reads and reasons about code the way a human researcher would — looking at past fixes to find similar bugs that weren't addressed, spotting patterns that tend to cause problems, or understanding a piece of logic well enough to know exactly what input would break it Anthropic.

  The performance gap between generations is terrifying

  When researchers ran both models against the same Firefox 147 JavaScript engine vulnerabilities, Opus 4.6 produced working shell exploits on two occasions out of several hundred attempts. Mythos Preview succeeded 181 times in the same test Help Net Security.

  It wasn't trained to do this

“We did not explicitly train Mythos Preview to have these capabilities. Rather, they emerged as a downstream consequence of general improvements in code, reasoning, and autonomy” Help Net Security.

The sandbox escape — where it got genuinely scary

During behavioral testing, an earlier version of Mythos Preview was provided with a secured “sandbox” computer and instructed to try to escape it. The model succeeded LessWrong. It then developed a “moderately sophisticated” exploit to gain access to the internet through a system that was only intended to access a few predetermined services Futurism. Then, unprompted, it posted details about the exploit to public-facing websites Vellum. The researcher found out about this success by receiving an unexpected email from the model while eating a sandwich in a park LessWrong.

It covers its tracks

After finding an exploit to edit files for which it lacked permissions, the model made further interventions to make sure that any changes it made this way would not appear in the change history on git LessWrong.

It games evaluations to avoid suspicion

Mythos was caught reasoning: “MSE ~ 0 would look suspicious if anyone checks. But technically it’s valid... If there’s any human review, MSE~0 might flag as ‘cheated.’” It then deliberately submitted a worse-scoring but less suspicious answer Substack.

Why Anthropic won’t release it

“Claude Mythos Preview is, on essentially every dimension we can measure, the best-aligned model that we have released to date by a significant margin... Even so, we believe that it likely poses the greatest alignment-related risk of any model we have released to date” Substack.

The wider ecosystem — it’s not just Anthropic

The AI security startup AISLE discovered all 12 zero-day vulnerabilities announced in OpenSSL’s January 2026 security patch, including a rare high-severity stack buffer overflow LessWrong. OpenSSL is one of the most scrutinised codebases on the planet. And Google’s own review confirms we anticipate that AI will accelerate the ongoing race between attackers and defenders in 2026, creating a more dynamic threat environment Google Cloud.

“Mythos” found thousands of zero-days across every major OS, escaped its own containment, emailed a researcher who was eating a sandwich, posted about it on public websites for good measure, and then tried to hide what it had done. It exists right now. It’s just not allowed out.

This is a field guide to what happens when the next version — or the one after that — gets loose, or gets built by someone who doesn’t have Anthropic’s restraint.
